

DAM Data pull Design

Some points to Remember-

- Storing the data at our end in a stage/tmp table till the time CRR process completes and it will have all sde tags in place for PII columns like cm11, cm13, cm15 etc.
- DAM has 2 diff types of table structure at their end-
 - a. Staging: In the staging layer, each demographic attribute—such as PEP, product, email, phone, and occupation—is maintained in a separate table. The data is structured with individual fields represented as distinct columns, allowing for straightforward data extraction. It only consists latest information pertaining to each account/customer relationship
 - b. ODL: The information from each staging table is consolidated into a single column using a nested JSON format. Each key within the JSON object corresponds to a column from the respective staging table. They contain historical records
- We will source the data from the ODL table instead of the staging table, as it contains historical records. For each execution, we will retrieve records where the dam_start_ts(column in dam table to maintain entry date of record in the table) is less than or equal to the trigger timestamp. From these, only the latest record for each entity—based on the maximum start timestamp—will be considered. Any data inserted into the table after the trigger timestamp will not be included in that execution.
- The reason for not using the staging table is that since it is full refresh, we risk losing data from the table that initially triggered the event change, especially if the table /or any of tables get refreshed between the trigger event's start timestamp and the actual DAM extraction process.
